It is a well-known fact that type 2 odontoid fractures frequently go into nonunion. If left untreated, patients may develop irreducible atlantoaxial dislocation (AAD). We describe the surgical management of two patients with neglected odontoid fractures and irreducible AAD treated with single stage anterior release followed by posterior instrumented fusion. Both patients presented with history of neglected trauma and progressive myelopathy. Traction under anesthesia failed to achieve reduction of AAD. Anterior release was done by trans-oral approach in one patient and retropharyngeal approach in the other. Posterior fixation was performed with transarticular screws in both the patients. Both patients had full neurological recovery and demonstrated fusion at follow-up. Anterior release followed by posterior instrumented correction may be an effective alternative to the traditional means of treating irreducible dislocations associated with neglected odontoid fractures.

Keywords: Atlantoaxial joint; Dislocation; Atlantoaxial dislocation; Neglected; Odontoid process

Introduction

Neglected spinal injuries are frequently encountered in the developing world. Overlooked diagnoses, poor accessibility to healthcare and socio-economic factors are the major reasons for such occurrences [1]. Often these injuries cannot be treated with conventional surgical techniques and require innovative ideas. As neglected spinal injuries are infrequently discussed in literature, we would like to present two cases of neglected odontoid fractures with irreducible dislocation and myelopathy. These cases

were treated with anterior release of contractures and/or structures blocking the reduction, followed by posterior C1–C2 fusion in single stage. We present the surgical technique and the outcome of these patients.

Technical Note

1. Case 1

A 24-year-old man presented to us with neck pain and progressive difficulty in walking with weakness in the

right hand since one month. One year ago he had injured his neck in a road traffic accident after a fall off a bike. He did not seek medical attention and claims that he did not

have any weakness at that time. He had torticollis with a right-sided head tilt, spasticity and exaggerated deep tendon reflexes in all extremities. Right hand grip was weak. Rest of the muscle groups had normal motor power. Sensations were preserved and the plantar response was extensor bilaterally.

Radiographs revealed rotatory atlanto-axial dislocation with anterior subluxation of atlas (Fig. 1A), which did not reduce on dynamic views. Computed tomography (CT) revealed nonunion of type II dens fracture (Fig. 1B). There was significant C1–2 kyphosis with a clivus-canal angle of 114° . The right sided C1–C2 joint was well aligned, however, the left side joint was dislocated and arthritic (Fig. 1C, D). This was probably the principal reason for the irreducibility. Magnetic resonance imaging (MRI) revealed severe cord compression at the craniovertebral junction with a cervico-medullary angle of 126° .

Skeletal traction was progressively increased up to 10 kg over 2 days preoperatively, but this failed to improve the alignment. The patient was taken for surgery and following general anesthesia and complete muscle paralysis, sustained skeletal traction up to 15 kg was given for ten minutes. This led to slight improvement in C1–2 kyphosis, but anterior translation of C1 could not be corrected (Fig. 2A).

1) Surgical technique

The neck was positioned in hyperextension under cervical traction. A transnasal catheter sutured to the uvula was used to retract the soft palate. Crockard transoral

retractor system provided a standard transoral exposure. The longus colli, longus capitis muscles and the anterior longitudinal ligament were transversely divided along the inferior border of the C1 arch. The anterior capsule of the atlantoaxial joint was incised. A 5-mm periosteal elevator was used to distract the atlantoaxial joint taking care to remain within the lateral edge (Fig. 2B). This released any intra-articular adhesions.

Following anterior release, the patient was carefully turned prone while maintaining skeletal traction. Posterior exposure of atlantoaxial region was then performed. A sublaminar wire was passed under C1 posterior arch. This was used to give a posteriorly directed force to achieve and maintain anatomical reduction while definitive fixation was performed. Trans-articular screws were used for fixation and autologous posterior iliac crest bone graft used for fusion (Fig. 2C).

2) Postoperative management

The patient was mobilised soon after surgery in a Philadelphia collar. Nasogastric tube feeding was continued for 7 days till the incision on posterior pharyngeal wall healed. Patient had a complete neurological recovery at the 3-month follow up visit. Radiographs at 24-month follow-up revealed maintained C1–2 alignment and good consolidation of the posterior bone graft (Fig. 3A). A CT at one year showed anatomical C1–2 alignment with a clivus-canal angle of 145° (Fig. 3B).

2. Case 2

A 9-year-old male child presented with gradually progres-

sive weakness in both hands and difficulty in walking of 3 weeks duration. He had a history of fall from height of approximately 10 feet, six months ago followed by injury to his neck for which no treatment was taken. On examination he had weakness of bilateral handgrip with spasticity and exaggerated deep tendon reflexes in all extremities. He had grade 4 to 5 strength in the rest of the muscle groups without any sphincter dysfunction. Sensations were intact to light touch.

Radiographs, including dynamic views, revealed irreducible atlantoaxial dislocation (Fig. 4A). Preoperative skeletal traction up to 6 kg did not achieve reduction (Fig. 4B). CT scan revealed type II dens fracture in nonunion. There was some new bone formation at the fracture site, which was probably one of the contributing factors preventing reduction (Fig. 4C). MRI revealed severe cord compression at the cranio-vertebral junction. Traction under anesthesia and complete muscle relaxation failed to achieve reduction.

1) Surgical technique

The patient had restricted mouth opening, hence anterior release was done via retropharyngeal approach. An oblique incision was taken between the thyroid notch and hyoid cartilage extending from midline to the lateral border of sternocleidomastoid muscle. Platysma was cut in line with the incision. The hypoglossal nerve runs parallel to the tendon of digastric muscle. It was dissected and protected. The sternocleidomastoid muscle and carotid sheath were retracted laterally. The strap muscles, hyoid and pharynx were carefully retracted medially to expose the retropharyngeal space. Following this the arch of C1 was palpated. A blunt instrument was placed on the arch of C1 and position was confirmed under fluoroscopy. Similar releases were carried out as described for Case 1. Fluoroscopic image after anterior release showed satisfactory alignment (Fig. 4D). The posterior instrumentation and fusion (Fig. 4E, 4F) was done using transarticular screws. A sublaminar wire was passed under C1 posterior arch. This was used to give a posteriorly directed force to maintain reduction while trans-articular screws were passed (Fig. 4E).

2) Postoperative management

Postoperative recovery was uneventful except for dysphagia that required a course of intravenous dexamethasone and nasogastric feeding for 3 weeks. The patient had a

complete neurological recovery at 3 months follow-up and X-rays showed bridging bone across posterior elements of C1–C2 at one year follow up.

Discussion

It is a well-known fact that type 2 odontoid fractures frequently go into nonunion. The reported rate in literature varies between 26% to 76% [2]. The instability caused by the fracture along with poor vascularity of this region, as it is enveloped in synovium, is proposed as a probable explanation of this occurrence. If left untreated, C1 eventually loses support from the C2 superior articular process. With time, the tissues in the concavity of the deformity,

which is ventral to the craniovertebral area, contract and shorten. The longus colli, longus capitis, anterior joint capsule and the anterior longitudinal ligaments are all in the concavity of the deformity (C1–C2 kyphosis) and undergo contracture preventing complete reduction.

In addition to soft tissue contractures, bony changes may also play a role in irreducibility. The articular surfaces of C1–2 may become gradually more vertical and arthritic preventing the reduction of atlas over axis. Furthermore, new bone formation between dens and body of axis may prevent posterior translation of dens hence preventing reduction of C1–2 joint. Arthritis of the C1–C2 joint (Case 1) and new bone formation at the fracture site (Case 2) were probably the reasons for irreducibility in our patients. In

rare cases malunion of the odontoid has been reported as the cause for irreducibility.

Traditionally irreducible atlantoaxial dislocations have been treated with transoral odontoidectomy followed by posterior fusion [3-5]. With technological advances in microsurgical techniques, the safety of transoral odontoidectomy has improved substantially. However, it is still technically demanding and carries a small but significant risk of incidental dural leak that may lead to meningitis. During transoral odontoidectomy no attempt is made to correct the atlantoaxial kyphosis or the rotatory malalignment. This may result in swan neck deformity in the cervical spine or residual torticollis respectively [6].

Posterior atlantoaxial joint release and distraction is an alternative described by Goel [7]. Although this procedure works well in the less severe irreducible dislocation, we have found it considerably difficult in achieving anatomical correction in patients with severe dislocation. In a patient with complete spondyloptosis of the C1 over C2 that is irreducible, we have found it difficult to access the C1-C2 joint from the posterior approach without sacrificing the C2 superior articular facet. This is similar to performing sacral dome osteotomy done to gain access in the spondyloptotic L5-S1 disc space in high-grade spondylolisthesis. In our experience, excessive drilling in this area results in loss of the C2 superior articular facet and its underlying bone making it difficult to place a C2 pedicle screw safely. Moreover, this technique of posterior distraction of facets fails to address the primary tether (contracted longus colli, longus capitis and the anterior facet capsule) in chronically dislocated joints.

Wang et al. [6] in 2007 showed that anterior transoral release of irreducible atlantoaxial dislocation followed by posterior instrumented fusion can achieve excellent alignment even in severe dislocations. Several authors have reported successful application of this technique to treat irreducible dislocations [8-10]. There are several advantages of this technique over transoral odontoidectomy. An anatomical reduction can be achieved preventing subaxial swan-neck deformity. Torticollis can be corrected. Transoral dural injuries and its associated morbidity can be avoided. The release of C1-C2 joints anteriorly also makes the posterior reduction maneuver technically easier. We propose that in patients in whom transoral odontoidectomy is planned, an initially release procedure under fluoroscopy should be attempted. If the release is unable to achieve adequate correction then the surgery can proceed

to odontoidectomy.

There are some reports of neglected odontoid fractures treated with this method [4,11-13]. Anterior release of contracted structures can be performed trans-orally or via retropharyngeal approach. Microendoscopic anterior release and video-assisted transcervical anterior release have also been described in the literature. Most surgeons prefer posterior fixation following anterior release; however, Wu et al. [11] described a technique of microendoscopic anterior release and anterior transarticular screw fixation for patients with irreducible atlantoaxial dislocation.

We used the transarticular screw fixation for posterior C1-C2 fusion. An alternative technique is to use the Goel Harms C1 lateral mass and C2 pedicle screw fixation. There are definite advantages of the latter technique over transarticular screws. Particularly, in the cases presented, the Goel Harms technique would have been technically easier as this method does not require anatomical reduction of C1-C2 joint before fixation. Rotational malalignment is also easier to correct with this technique.

In conclusion, neglected nonunion of odontoid fracture may lead to irreducible dislocation. Anterior release followed by posterior instrumented correction may be an effective alternative to the traditional means of treating irreducible dislocations.
